#### Abstract

The vital stain fluorescein diacetate (FDA) has long been used to assess the viability of *Erysiphe necator* ascospores in chasmothecia. To determine the viability of animal, plant and other cells, more complex staining procedures, for example simultaneous double-staining procedures based on the use of FDA and propidium iodide (PI), have also been widely used. This paper reports a refined version of this method, where PI was replaced with ethidium bromide (EtBr), to be used in testing the viability of *E. necator* ascospores during overwintering in chasmothecia.

**Keywords**: grapevine powdery mildew; fluorescein diacetate; ethidium bromide; propidium iodide; epifluorescence microscopy

The question whether ascospores remain viable during, and after, overwintering of *Erysiphe necator* chasmothecia (formerly known as cleistothecia) has long been an important issue because of previous controversies about the role of chasmothecia in the life cycle of the grapevine powdery mildew fungus (Pearson & Gadoury 1987; Cortesi et al. 1997; Rossi et al. 2010). The vital stain fluorescein diacetate (FDA) was used in several works to detect living *E. necator* ascospores (e.g., Gadoury & Pearson 1991; Cortesi et al. 1995; Evans et al. 1997; Miazzi et al. 2003; Hajjeh et al. 2008) based on a method originally reported by Widholm (1972) to test the viability of plant cells. FDA was also used to verify the viability of *E. necator* hyphae on grapevine berries (Ficke et al. 2002) and leaves (Moyer et al. 2010), thus this stain has been largely applied in the study of the grapevine powdery mildew fungus.

To determine the viability of fungal, animal, plant and other cells, more complex staining procedures have also been widely used. For example, FDA was successfully combined with propidium iodide (PI) to develop a simultaneous double-staining procedure for animal cells (Jones and Senft 1985). A similar method based on staining with FDA and PI was developed to distinguish viable and dead bacteria, and the method was successfully tested with spores of different fungal species, as well (Chen and Séguin-Swartz 2002). We refined this method, and replaced PI with ethidium bromide (EtBr), to be used in testing the viability of *E. necator* ascospores during overwintering in chasmothecia. EtBr and PI performed equally well in our tests; EtBr was preferred because its availability is more widespread in laboratories compared to PI. Here we present a detailed report of our procedure adapted to powdery mildew research to supplement earlier descriptions which did not provide all the fine points, and limits, of the methodologies used, and were based on the use of FDA

only. Our method consisted of crushing chasmothecia on microscope slides directly in a droplet of a solution containing FDA and PI, both at a working concentration of 20  $\mu$ g/ml. This solution was always freshly prepared by diluting 20x a 1 mg/ml FDA stock solution in acetone, using phosphate-buffered saline (PBS) or distilled water, and adding EtBr to reach the final concentration of 20  $\mu$ g EtBr/ml in the solution. Slides were incubated in dark at room temperature for 5 min and then checked immediately under a Nikon Eclipse 80*i* epifluorescence microscope. The EtBr signal was detected using the filter cube with 540/25 nm excitation, 565 nm dichroic mirror, and 605/55 nm barrier filter. FDA fluorescence was detected with another filter cube with 465-495 nm excitation, 505 nm dichroic mirror, and edited and merged with the Adobe Photoshop software.

FDA is lipophilic, membrane-permeable, non-fluorescent, and it is hydrolyzed to polar fluorescent molecules in the cytoplasm of living cells. These molecules remain in the cytoplasm of living ascospores with intact cell membranes and exhibit intense green fluorescence when excited with blue light (465-495 nm); lights with other wavelengths can also be used to make these molecules fluoresce. In contrast, EtBr can only penetrate dead, or dying, cells with damaged plasma membranes and intercalates into double-stranded nucleic acids, thus mainly emits fluorescence from the nucleus, in addition to some background fluorescence which was also helpful to visualize cells and asci in our samples. We used green light, i.e. the Nikon 540/25 nm excitation filter, to detect an intense orange EtBr signal from dead or dying *E. necator* ascospores; lights with other wavelengths can also be used to excite EtBr.

Although after the dual staining with FDA and EtBr it is possible to observe the fluorescence signals from both dyes simultaneously, as recommended by Jones and Senft (1985), in case the microscope is equipped with a proper dual band fluorescence filter set, we

found more useful to observe first the FDA signal alone, using the blue light excitation, and then the EtBr signal only, following excitation with green light. This two-step observation procedure was more straightforward because a part of the living ascospores were damaged 6 to 10 min after crushing the chasmothecia on microscope slides, probably partly due to their exposure to heat and also to the mixed FDA and EtBr solution containing acetone. Consequently, in a part of the ascospores exhibiting bright green fluorescence at the beginning of the microscopic observations (Figs. 1A-C), and no EtBr signal at all, a few minutes later the nucleus started to fluoresce in orange when EtBr was excited (Figs 1D-E), indicating that the cell membranes became damaged as a result of the experimental procedure. These ascospores were always counted as living ones when the number of viable and dead ascospores was determined. Those ascospores which emitted the EtBr signal only, right from the beginning of the epifluorescent examination of a sample (Figs. 1E-F), were considered as dead in the examined sample. Merged pictures (Figs. 1G-I) were also produced to make the distinction between viable and dead ascospores more clear. In some cases living ascospores remained viable, showing green fluorescence only, for a long time, more than 10-15 min after the start of the microscopic observation (Fig. 1F).

The refined double staining method provided more information compared to the FDA staining alone because in this way it was possible to determine the number of dead ascospores, as well, which were not visible when only the FDA signal was observed (Figs. 1E-F). The FDA staining alone did not result in much background fluorescence, in contrast to the EtBr (or PI) staining. The orange background EtBr fluorescence, in addition to the intense orange fluorescence of nuclei in the dead, or dying, ascospores (Figs. 1D-F), contributed to a better visualization of the samples. This is a clear advantage of the method when pictures are examined with a software for image analysis.

Another advantage of the double staining procedure was that technical problems with FDA staining did not remain overlooked. In some cases, FDA was simply not metabolized by a part of the presumably viable cells, and, thus, these did not show green fluorescence, due to some technical problems. These cells did not exhibit the EtBr signal either, indicating a procedural matter; in these cases we always repeated the double staining with another subset of the respective sample and usually got reliable results. Such technical issues, i.e. false negative results, cannot be detected if FDA is the only stain used, and cell viability is simply assessed by switching from brightfield to fluorescence microscopy to determine the ratio between the viable vs. the total number of spores. Based on these considerations, the simultaneous FDA and EtBr staining procedure proved to be the best choice for ascospore viability assessments in overwintering chasmothecia of *E. necator* and this method can be recommended for other plant pathological studies, as well.
