Funding source: Funding for this study was provided by Health Collaboration Research Network (CRN). The funder played no role in the design, collection, analysis or interpretation of the data, writing the manuscript, or the decision to submit the paper for publication.

Contributors: Belinda Goodwin conducted literature searches, collected the data, conducted analyses and wrote the first full draft of the paper. Dr Matthew Browne conducted the main analysis and was instrumental in editing content. Professor Matthew Rockloff and Dr Natalie Loxton, assisted in developing the research question, contributed to and edited the manuscript, providing expert advice.

Conflicts of Interest: All authors declare that they have no conflicts of interest.

ABSTRACT

Background and aims

Impulsivity has consistently been associated with over-consumption and addiction. Recent research has reconceptualised impulsivity as a two-dimensional construct (Dawe, Gullo & Loxton, 2004). The present study explores the relationship of the two components of impulsivity, reward drive (RD) and rash impulsivity (RI), on a broad group of 23 hedonic consumption behaviours (e.g., gambling, substance use, eating, media use). We tentatively grouped the behaviours into three descriptive classes: entertainment, foodstuffs, and illicit activities and substances.

Results

RD and RI positively predicted elevated levels of consumption in a community sample (N = 5391; 51% female), for the vast majority of the behaviours considered. However, the effect sizes for RD and RI varied significantly depending on the behaviour; a pattern that appeared to be at least partially attributable to the class of consumption. Results support the view that RD is related more strongly to the consumption of products that provide social engagement or a sense of increased status; whereas RI better reflects an approach toward illicit or restricted products that are intensely rewarding with clear negative consequences.

Conclusions

Results support the utility of the two-factor model of impulsivity in explaining individual differences in patterns of hedonic consumption in the general population. We discuss findings in terms of strengthening current conceptualisations of RI and RD as having distinct implications with respect to health-related behaviours.

Keywords: reward drive; rash impulsivity; consumption; health behaviour; hedonic stimuli.

INTRODUCTION

Research into health behaviour and addiction has explored a broad range of hedonic products that tend to elicit excessive consumption that can lead to harm. These typically include products such as foods (Davis & Carter, 2009), illicit substances (Darke et al., 2008; McGlothlin & West, 1968; Rehm, 2011), and retail goods (Sansone, Chang, Jewell, & Sellbom, 2012). More recently, the use of certain entertainment and media products have been considered as forms of consumption behaviour (Noor, Roser, & Erickson, 2014; Rockloff, 2011; Ward & Carlson, 2013), with much research now focusing on excessive or problematic use of digital media, and gambling products (Morahan-Martin, 2005; Pentz, Spruijt-Metz, Chou, & Riggs, 2011; Rockloff, 2011; Takao, Takahashi, & Kitamura, 2009). Impulsivity is consistently associated with excessive and unhealthy levels of various forms of consumption. Examples include food (Kane, Loxton, Staiger, & Dawe, 2004; Moreno-López, Soriano-Mas, Delgado-Rico, Rio-Valle, & Verdejo-García, 2012), substances (Petry, 2001), gambling products (Benson, Norman, & Griffiths, 2011; MacLaren, Fugelsang, Harrigan, & Dixon, 2012; Petry, 2001), retail goods (Billieux, Rochat, Rebetz, & Van der Linden, 2008) and digital media (Billieux, Van der Linden, & Rochat, 2008; Dong, Huang, & Du, 2011).

Impulsivity, broadly defined, reflects a tendency to engage in behaviour in a rash manner that lacks foresight, reflection, or long term planning. However, varied measures of impulsivity (derived from different theoretical backgrounds) have been applied across previous studies of personality (Dawe, et al., 2004). For example, Gray (1981; 1970) defined the construct in terms of individual differences in sensitivity and approach to reward, whereas other definitions of impulsivity describe rash unplanned behaviour, risk taking, and novelty seeking (Cloninger, 1987; Eysenck & Eysenck, 1991; Zuckerman, 1978). Whiteside and Lyman, (2001) described a multi-factor model of impulsivity based on the factor analysis of self-report questionnaire data. Factors include urgency, lack of premeditation, lack of

perseverance, and sensation seeking (UPPS; Whiteside & Lyman). More recently, conceptualizations of impulsivity, particularly as related to addictive behaviours, have focused on two distinct dimensions based on separate neural processes (Dawe & Loxton, 2004; Gullo, et al., 2014) and recent factor analytic studies suggest that impulsivity is likely to be a multi-dimensional construct, consisting of at least two correlated factors (Dawe, et al., 2004). While both conceptualizations share similarities, it has been demonstrated that the two-factor model is the more parsimonious approach for understanding addictive behaviours (see Gullo et al., 2014).

In the two factor model, the first factor is termed rash impulsivity (RI); involving difficulty inhibiting one's behaviour following the activation of an approach response, despite potential negative consequences. The second is reward drive (RD); the tendency for one to initiate goal-directed approach behaviour in response to signals of reward. RD is thought to involve the mesolimbic dopaminergic pathways; a brain region associated with natural reinforcement responses to nutrients and reproduction. It is thought that RI reflects activity in the orbitofrontal cortex and the ventromedial prefrontal cortex; areas associated with self-control and decision-making (Dawe, et al., 2004).

RI and RD share many common features, including a positive relationship with addictive and hedonic behaviours (Dawe, Gullo, & Loxton, 2004; Dawe & Loxton, 2004; Dissabandara et al., (2014); Gullo, Loxton, & Dawe, 2014). Nevertheless, conceptually they describe complementary aspects of impulsivity relating to heightened approach (RD), and decreased inhibition (RI). RD is distinguished from RI in that high RD individuals report greater psychological well-being and hope, experiencing greater sociability and less loneliness – with RI being associated with less positive outcomes (Carver & White 1994; Clark, Loxton, & Tobin, 2015; Harnett, Loxton, & Jackson, 2013).

Only a few studies have taken the two-factor approach to measuring impulsivity; justifying the need for assessment of the unique roles of RD and RI in potentially determining consumption behaviour of both addictive and non-addictive products. When entered simultaneously in regression models, RI and RD both explain unique variance in gambling, alcohol use, and drug use, although RI appears to be the stronger predictor of the two (Gullo, Ward, Dawe, Powell, & Jackson, 2011; Loxton, Nguyen, Casey, & Dawe, 2008; MacLaren et al., 2012). Studies linking impulsivity to addictive behaviour have mainly aimed to predict clinical levels of only one or two specific behaviours, focusing on addictive substances and problematic behaviours. For example, Dissabandra et al., (2014) compared levels of RD and RI between heroin dependant subjects (n= 293) and non-users (n=232), and Guerrieri, Nederkoorn, and Jansen, (2008) assessed reward sensitivity, response inhibition, and food intake in normal versus obese children. To date, little research has focussed on sub-clinical levels of consumption in the general population. Thus whilst RD and RI have been shown to play unique roles in the susceptibility to clinical levels of addictive behaviour, it remains an open question as to whether these results apply to sub-clinical levels of over-consumption in the general population. In addressing this question, we are able to better understand the effect of impulsivity on minor levels of over-consumption that effect a substantial proportion of the general population (Sussman, Lisha, & Griffiths 2011). In addition, although theoretical conceptualisations of RD and RI imply differing relationships to qualitatively different types of behaviour (e.g. social engagement versus risk taking), these predictions have hitherto not been specifically tested. More generally, little is known regarding the role of RD and RI in determining (mal)adaptive or (un)healthy patterns of consumption in the general population.

Current Study

This paper considers RD and RI with respect to the day-to-day consumption of a wide range of hedonic products in a community sample. We focus on elevated usage levels in the

general population, rather than discriminating clinical versus non-clinical levels. In order to concisely describe our predictions and findings regarding this wide range of variables, we group products into three tentative classes: foodstuffs, ‘illicit’ activities including stigmatized or restricted / risky behaviours, as well as ‘entertainment’ – a product category of modern media and economic consumption. Table 1 summarises the measured items. Although products were categorised in this way for descriptive purposes only, a confirmatory factor analysis showed that item loadings were positive and, for the most part, homogenous on their allocated factors. An RMSEA of .065 [95% CI = .063, .066] suggested that this model fitted the data well.

Insert Table 1

Since general impulsivity is associated with various forms of hedonic consumption (Benson, Norman, & Griffiths, 2011; Billieux, Van der Linden, & Rochat, 2008; Dong, Huang, & Du, 2011; Kane, et al., 2004; MacLaren, et al., 2012; Moreno-López, et al., 2012; Petry, 2001), we expect that RD and RI should be associated with above average consumption of all behaviours listed in Table 1. According to current the conceptualization of the two-factor model, trait RD reflects goal-directed approach behaviour (Dawe et al., 2004) and is associated with higher sociability and psychological well-being (Clark et al., 2015; Harnett et al., 2013). On the other hand, RI more likely reflects a lack of control (Dawe et al., 2004) and is associated with higher consumption of products providing intense reward with clear negative consequences (Gullo, et al., 2011; Loxton et al., 2008; MacLaren et al., 2012). Therefore, we expect that RD will have a stronger association with the consumption of products classed as entertainment, which includes a range of activities that provide reward through experiences of social interaction; or increased social status via acquisition of wealth or assets. Notably, the behaviours in the entertainment category tend to involve some level of social or economic engagement, and are either socially accepted or even encouraged. RI, on

the other hand, should show stronger associations with the more intensely rewarding and potentially more dangerous products in the ‘Illicit’ category. These are products that are widely recognized to provide short-term rewards at the expense of potential long-term harms, and should therefore be related to a lack of control and planning. It is less clear whether RD or RI is more important in explaining variability in food consumption. Although many experience a lack of control and long-term harms from excessive eating, foods tend to provide only moderately intense short-term rewards. Also, food consumption tends to have a strong social component (e.g. dining with family or having coffee with friends), and tends not to be socially proscribed. Therefore, we expect that both RD and RI may play a relatively equal role in predicting above average food consumption.

METHODS

Survey Participants and Procedure

Data for the current study was collected as part of a large research project, results involving the consumption items and the RD and RI variables have been published previously in separate manuscripts (Goodwin et al., 2015b, Goodwin, Browne, Rockloff, & Loxton, 2016, respectively). Participants consisted of 5391(51% female) members of an online survey panel maintained by an agency specializing in the recruitment of survey participants (myopinions.com.au). Participation was remunerated with credit points that could be accumulated and exchanged with the agency for cash. The survey took approximately 20 minutes to complete. Ages ranged from 18 to 87 years old ($M=49.01$, $SD=16.50$). Participants were born in Australia (74%), the United Kingdom (8.4%), New Zealand (2.7%) and other countries (14.9%).

Measures

Behavioural Items: Behavioural items represented the consumption of a range of hedonic stimuli including energy dense foods and beverages, illicit and/or restricted substances, and

various retail and/or media. The brief AUDIT C (Bush, Kivlahan, McDonell, Fihn, & Bradley, 1998) and the Consumption Scale for Problem Gambling (CSPG; Rockloff, 2011) were utilized as validated measures of alcohol and gambling consumption. A further 21 variables were aggregated from a set of 31 additional novel items. Appendix Table 1 details each of the items that were summed to create each variable. Items were recorded on Likert scales (see appendix table 1), whereby the middle category represented an approximate average based on, where available, population norms (Goodwin et al., 2015b). The behavioural variables were converted into binary indicators of ‘above typical consumption’ based on a median split. Whilst this transform results in some loss of information and power, it provided for an identical scale across all responses and enabled the use of a consistent analysis (logistic regression) in all cases, facilitating comparisons of effects across behaviours.

Insert table 1

Rash Impulsivity: Rash impulsivity was measured using a short version of the Barratt Impulsivity Scale (BIS-11; Spinella, 2007). This measure consists of 15 statements, whereby the participant must rate the extent to which the statement applies to them. Responses are recorded on a 4-point Likert scale (1, Rarely/never; 2, Occasionally; 3, Often; 4, Almost always/always). The measure includes three subscales; Attentional (e.g., “*I don’t pay attention*”), Motor (e.g., “*I act on the spur of the moment*”), and Non-planning (e.g., “*I am a careful thinker. [inverted]*”). The total BIS-11 score was utilized in the current study. Cronbach’s alpha in the present sample was .83

Reward Drive: The Behavioral Approach Scale (BAS) from the Behavioural Inhibition and Approach Scale (BIS/BAS; Carver & White, 1994) was used to measure RD. This 13 item measure involves three subscales 1) Drive, assessing a persistence in pursuing desired goals (e.g., “*When I want something, I usually go all out to get it*”), 2) Reward Responsiveness

scale, focused on the response to occurrence or anticipation of reward (e.g., “*When I’m doing well at something, I love to keep at it*”), and 3) Fun seeking (e.g., “*I crave excitement and new sensations*”). Responses were recorded on a 4-point Likert scale (1, Rarely/never; 2, Occasionally; 3, Often; 4, Almost always/always). The total BAS score was utilized in the current study. Cronbach’s alpha coefficient in the current study was .88.

Ethics

The study received Human Research Ethics Committee approval from the university’s review board and participants provided informed consent preceding the online survey.

Statistical analysis

A series of multiple logistic regressions were performed with reward drive and rash impulsivity predicting above median consumption on each of the measured products. Each model controlled for gender, age, income, and the shared variance between RD and RI ($r = .27, p < .001$). A false discovery rate (FDR) adjustment was applied to significance values to reduce the probability of a Type I error when running multiple analyses (Benjamini & Hochberg, 1995). The authors also ran another series of regressions whereby each model included the interaction term, RD by RI. No significant interaction effects were found, therefore only main effects are presented in the results section.

RESULTS

Gender, age, and income effects

Table 2 compares gender, age and income group means for each of the measured behaviours. Women were significantly higher consumers of many entertainment products; including watching television, reading advertising brochures, retail products, magazines, social networking, SMS, and online shopping products. Men consumed more of the illicit products along with some of the food items (e.g., pornography, cigarettes, alcohol, gambling

products, drugs, caffeine, soft drink, meat products, take away food, and packaged food).

Using a median split, those 51 years of age and under reported significantly higher consumption of most products, as did participants who earned over \$65K per year. However, those earning \$65K or under reported significantly more television viewing, smoking of cigarettes, and reading of advertising brochures.

Insert Table 2.

Regression of consumption behaviours on RD and RI

As shown in Table 3, RD significantly and positively predicted 19 of the 23 consumption behaviours, with the exception of smoking, packaged food, television and meat products (marginal). The strongest of these associations were between RD and frequency of: browsing online (standardized $\beta = .238, p < .001$), SMS ($\beta = .223, p < .001$), using social networking ($\beta = .213, p < .001$), viewing pornography ($\beta = .174, p < .001$), and consumption of caffeine ($\beta = .178, p < .001$). RI significantly and positively predicted 18 of the consumption behaviours, with exception of reading junk mail, eating dessert, shopping (marginal), reading magazines, and browsing online. The strongest of these associations were between RI and using drugs $\beta = .512, p < .001$, gambling ($\beta = .283, p < .001$), alcohol ($\beta = .235, p < .001$), buying packaged food ($\beta = .206, p < .001$), and eating take away food ($\beta = .190, p < .001$). Finally, the binarized behavioural responses were aggregated using a simple count; yielding a variable that described the number of behaviours (out of 23) that individuals undertook at above-median levels. Using OLS regression this ‘total consumption’ variable was predicted positively by both RD $\beta = .645, p < .001$ and RI $\beta = .604, p < .001$.

Insert Table 3.

Figure 1 plots the standardized beta weight for rash impulsivity and reward drive for each behavioural item. Items are coded according to Table 1 as Entertainment, Foods, or Illicit, representing the three classes of stimuli measured. Items with asterisks above the

broken diagonal line (i.e., browsing online, brochures, magazines, snacks, dessert, shopping, SMS, and social networking) share significantly stronger associations with RD when compared to RI according to Fishers exact test for comparing parameter estimates, and those below the line (i.e., Internet, soft drink, TV, packaged foods, alcohol, gambling, smoking and drugs) share significantly stronger association with RI.

DISCUSSION

The key study aim was to understand the relationship between the dimensions of the two-factor model of impulsivity and hedonic product consumption. In particular, we were interested in the differential effects of RD and RI on the consumption of a wide range of qualitatively different products. RD and RI were both positively associated with above-average consumption of almost all of the measured behavioural items. As expected, RI shared its strongest associations with the intensely rewarding and potentially dangerous products classified as Illicit (e.g., alcohol, drugs, & gambling products). Both RD and RI tended to share small to moderate associations with food items whilst RD shared its strongest associations with the consumption of products classed by the current authors as entertainment.

In accordance with previous findings on clinical samples, people high in RI and RD reported higher levels of consumption. Thus, RD and RI appear to be not only useful in predicting addictive or disordered behaviours (Dissabandara et al., 2014; Kane, et al., 2004; Loxton, Nguyen, Casey, & Dawe, 2008), but also in explaining elevated consumption in the general population. Nevertheless, with the exception of illicit drugs, the effect sizes for RI and RD tended to small to moderate. This is not especially surprising, since like other high-level personality constructs, RD and RI can be understood to have a ‘diffuse’ effect on behavior; i.e. they have a small but measurable influence across a broad domain of specific behaviours. Given that unhealthy lifestyle choices are known to co-occur (be co-morbid) in

individuals, we have grounds to suspect that personality traits such as RD and RI are instrumental in explaining these multivariate co-morbidities. Whilst impulsivity may be a relatively minor influence on any given behavior, the aggregate impact of RD and RI on one's total health and wellbeing may be significant.

As illustrated in Figure 1, beta coefficients for RD and RI vary markedly across the behaviors considered in this study. Our specific predictions regarding the relative strength of RD and RI with behaviours in the three different descriptive classes were largely supported. That is, above-average consumption of most items categorized as illicit, including cigarettes, gambling products, alcohol, and drugs, shared significantly stronger associations with RI than RD. Most food products measured (i.e., meat, salt, sweets, dessert, snacks, and caffeine) did not have significantly different association with RD when compared to RI. Finally, entertainment items, including browsing online, sending SMS, social networking, reading magazines, and shopping), all shared significantly larger associations with RD.

These findings strengthen current conceptualizations of RD and RI. RD has been associated with socially driven behaviours (Clark et al., 2015) as well as more reflection and planning in approach to reward (Dawe et al., 2004). This is consistent with the pattern of effects seen here, in which RD predicted behaviours that tend to take relatively more cognitive effort, involve less immediate reward and more socially positive consequences. This may be seen in relatively stronger effects for the different forms of economic consumption, or communicating via digital media activities that generally take some planning and reflection, and lead to longer term rewards in terms of feelings of social interaction, affluence, or increased social standing. The relatively weaker effect observed for RI is understandable, given that it is conceptualized as a lack of control despite negative consequences (Dawe et al., 2004). This description is also consistent with the finding that RI was relatively more strongly associated with increased consumption of gambling, alcohol,

smoking, and substance use; behaviours that provide immediate and intense reward for very little effort, and for which the negative consequences are serious and well known (e.g., addiction, over-dose, and bankruptcy). RD and RI appear to be both independently associated with increased consumption, which can potentially be maladaptive, regardless of the product. However, our findings also support the notion that RI is most strongly associated with more unhealthy, risky forms of consumption.

There were some notable exceptions to these patterns, where items did not conform to expectations based on their allotted category. For example, TV, video-gaming and Internet were more strongly predicted by RI than RD. In part, this reflects previous study findings linking self-regulation and impulsivity to Internet use (e.g., Billieux & Van der Linden, 2012) and video-gaming (Billieux et al., 2011). It may be that, although these activities often mimic social interaction (in the case of games), or provide for hedonic social observation (in the case of TV), they often lack the features of active social engagement that other items in this category possess. In addition, being related to RI but not RD, packaged food consumption did not conform to the same pattern of results as other food items. This may be due to the fact that the appeal of this product lies more in the quick satisfaction of a craving (hunger), rather than being particularly hedonically rewarding.

Limitations

This cross-sectional survey had several specific limitations connected with the goal to simultaneously assess a wide range of hedonic consumption behaviours. Due to the need to keep the total survey time reasonable, many behavioural measures were measured using just one or two items, which can be expected to lead to diminished effect sizes due to measurement error. Furthermore, predicting specific behaviours from general personality traits is known to suffer from a mismatch in levels of description, which also contributed to lower effect sizes (Epstein, 1979). The large sample size employed was designed to partially

compensate for these two issues. R^2 values from the current study, although small, in many cases were comparable to those from similar studies predicting actual behaviour from personality traits (Gullo et al., 2011; Dawe & Loxton, 2001; Stojek et al., 2014). In addition, with the exception of alcohol and gambling, behavioural variables were measured using novel, self-report items that did not belong to a previously validated scale. This was somewhat compensated by the fact that items directly measured frequency of product consumption, reducing uncertainty around construct validity.

It is important to note that in this study the BAS and BIS-11 were applied as broad measures of RD and RI. Each scale is made up of subscales that are likely to be differentially associated with the hedonic behaviours. RD as a construct continues to be refined and a new revised scale has been recently developed based on revised reinforcement sensitivity theory (rBAS; Jackson, 2009). This revised scale assesses the more functional aspects of reward drive (Clark et al., 2015; Harnett et al., 2013; Jackson, 2009; Jackson, Loxton, Harnett, Ciarrochi, & Gullo, 2014) and has less in common with rash impulsivity. The measure of the original BAS used in the current study tends to correlate more so with rash impulsivity due to the inclusion of a 'fun seeking' scale. Although the aim of the current study was to predict hedonic consumption based on the broader constructs of RI and RD, future research might benefit from applying the updated BAS scale and investigating sub scale effects as this may result in more pronounced unique effects of the two factors of impulsivity and a more detailed understanding of these effects. Furthermore, consumption of hedonic stimuli is often used as a form of 'self-medication' due the stimuli's effect on reward centres in the brain (Markou, Kosten, & Koob, 1998; Tuomisto et al., 1999). The current research did not control for factors such as depression, anxiety, and positive and negative affect and further research is recommended to identify the impact these emotional and mood states/traits might have on the current findings.

Conclusion

To date, research into the effects of impulsivity on behaviour has focused on single pathological or disordered behavioural outcomes. Furthermore, the recently realised, two-factor model of impulsivity has been under-used in such research. Our results suggest that the two-factor model of impulsivity has relevance in explaining a wide range of consumption behaviours in the general population. Taken in the aggregate, across both behaviours and individuals, these traits may play a significant role in determining health outcomes. Our findings strengthen current conceptualisations of RI and RD. Results supported the interpretation that RD reflects reward approach in a reflective, socially driven manner, whereas RI reflects an approach to intense reward that lack controls and consideration for negative consequences. Excess consumption in the general population contributes to debt, emotional strain, and a variety of avoidable diseases. Understanding the psychological factors underlying an individual's vulnerability to excessive consumption should play a useful role in future public health initiatives and research.

*** = p<.001, ** = p<.01, * = p<.05, ^ = marginal. Variables sorted according to beta weight association with RD.

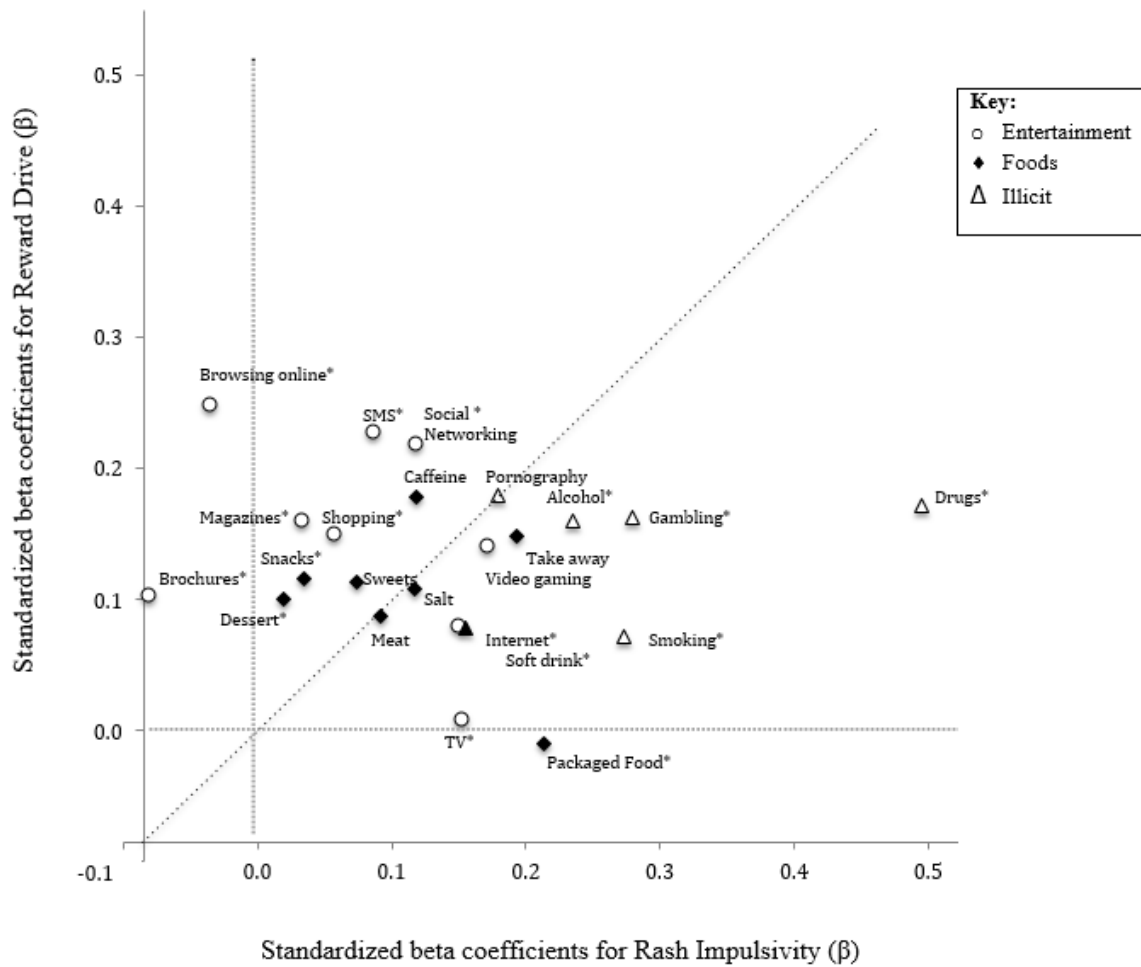

Figure 1. Scatterplot of rash impulsivity and reward drive standardized beta weights from regression analyses for each behavioural item, *difference between RD and RI beta weight significant at $p < .05$.

Appendix B: Consumption behaviour measures: Items included in each variable and response scales

Variable	Question	Response Scale
	<i>On a typical WEEK DAY/WEEKEND or WORKING DAY/NON-WORKING DAY*, how much time do you spend doing each of the following:</i>	1= none, 2 = < 10 mns, 3 = 10 – 30 mns, 4= 30mns to 1 hr, 5= 1-3 hrs, 6 = 3-5 hrs, 7 = 5 -7 hrs, 8 = 7+ hrs
TV	- Watching TV	
Internet	- Browsing the internet on a computer, smart phone or tablet	
Social		
Networking	- Using social networking websites (such as Facebook, Twitter or My Space)	
Pornography	- Viewing erotic or romantic images, videos or books	
Video Gaming	- Gaming on a desktop computer, game console, portable gaming system, mobile phone or tablet?	
	<i>On average how often do you do the following:</i>	1 = never, 2 = < once a wk, 3 = 1-2 per wk, 4 = 5-7 per wk, 5 = twice a day, 6 = 3 + per day
Take away	- Purchase foods for a meal or snack from fast food outlets such as KFC, MacDonald's, Hungry Jacks, Red Rooster	
Take away	- Purchase foods for a meal or snack from other food outlets such as a, bakery, service station, ... Chinese food, etc	
Desserts	- Eat desserts such as ice-cream, cake and cookies
