Abstract

An experimental and numerical investigation was undertaken to characterise the collapse of 3D orthogonal woven carbon fibre composites during the load cases of in-plane tension, in-plane compression and out-of-plane bending. Two different fibre architectures, varying only by the density of through-thickness reinforcement, were investigated. Cantilever beam tests were carried out to isolate two distinct collapse mechanisms, i.e. bending governed and shear governed deformation. A qualitative comparison was made with a similar UD-laminate material. 3D woven composites exhibited significantly reduced delamination. An investigation into the efficacy of an embedded element modelling strategy for in-plane tension, in-plane compression and out-of-plane bending load cases was undertaken. The predictions were generally in good agreement with the experimental measurements for the in-plane and out-of-plane loading.

1. Introduction

Three-dimensional woven composites contain woven textile reinforcement with yarns orientated along the x-axis, the y-axis and the z-axis. They have a distinct advantage over two-dimensional fibre reinforced composites due to their enhanced inter-laminar and flexure properties. The in-plane response has been investigated at depth within the literature. Prominent examples include the tensile properties [1-8], and the compressive properties [1, 9, 10]. However, the principle reasoning behind the addition of the through-thickness reinforcement is to improve the inter-laminar and out-of-plane bending properties of the composite.

The double cantilever beam (DCB) is an effective methodology for determining the Mode I inter-laminar fracture toughness of fibre reinforced composites. The DCB studies on 3D woven carbon/epoxy materials recorded increases in Mode I inter-laminar fracture toughness up to 15 times than that of a 2D carbon/epoxy laminate [11] and greatly increased strain-energy release rates of 3D composites in comparison to 2D composites [12]. This increase was attributed to crack-bridging and crack-diverting. Mode II inter-laminar fracture toughness is commonly measured via the end loaded split (ELS) [13-15] and three [16, 17] and four-point [15, 18] end notch flexure (3ENF and 4ENF) testing methodologies. ELF and 4ENF experiments undertaken upon 3D woven composites have suggested that there is a relatively greater role for the matrix in Mode II crack propagation in comparison to Mode I crack propagation, and therefore increases of binder density present a relatively lower increase in Mode II toughness. [15].

The flexural properties of fibre reinforced composite materials are commonly investigated in two standard tests: three-point bending tests [1, 19-24], and four-point bending tests [23-26]. During three-point bending tests, stress concentrations have been reported to cause early-

onset microcracking of the matrix and subsequent localised non-linearity [20], potentially leading to catastrophic failure of the beam [27]. The load concentration of the three-point bending test leads to a combination of bending with shear stresses [27], causing difficulty in the isolation of either one. Also, for composites with high levels of orthotropy, both a flexural and a twisting curvature is introduced throughout the beam length, which adds to the complication during three-point bending tests [28]. The four-point bending test is an attractive alternative as it induces pure bending stresses within the beam. However, due to rotation at loading rollers during four-point bending, the load span increases during the test, overestimations of flexural modulus are common if corrections are not made [25].

Gerlach et al. [21] investigated the out-of-plane properties of a through-the-thickness angle interlock 3D woven carbon composite material with a three-point bending test and plate bending test. The results indicated that binder density influences delamination length, however, the tests were highly dependent on support conditions and loading roller geometry. Zhang et al. [29] investigated a layer-to-layer orthogonal interlocked textile composite under three point bending, employing DIC to capture local increases in strain and microcracking. However, due to the localised damage initiation experienced in textile composites, interpretation of a catastrophic failure event during a three-point bending test can be complicated by the asymmetric nature of the failure; damage could occur in either or both of the two arms of the beam. Damage could also occur under the loading roller, complicating damage progression analysis [30]. Liu et al. [31] applied a cantilever beam test procedure to Dyneema material. This method proved useful in simplifying the analysis of beam collapse under bending. The research presented here adopts the cantilever beam test in order to activate two distinct collapse mechanisms for 3D woven carbon/epoxy composite materials. It then provides a clear analysis of the progression of the collapse event throughout the test

coupon. This is supplemented with further investigation into the two collapse modes via the use of the Finite Element (FE) method.

A common methodology in the numerical prediction of the stiffness and strength of woven composites is the FE analysis at a unit cell level [32-38]. Nagai et al. [32] used micro-mechanical FE analyses at the unit cell level in order to present a structural analysis model. The unit cell, composing of fibre (beam) elements and matrix (beam and rod) elements, was imparted with an enforced displacement in order to extract the non-linear properties. These properties were then translated to homogenous solids for use in the structural analysis for tensile, compressive and shear mechanical behaviour up to failure. The structural analysis model was used exclusively for undulated fibre composites, and was validated through experiments. Huang et al. [37] conducted a 3D multi-unit cell FE simulation in order to investigate the compressive strength and failure mechanisms of woven textile composites. They found that 16 unit cells gave good agreement to experimental results [37]. Kink band formation was determined as the main compressive strength limit factor [38]. Modelling at the representative volume element (RVE) level is an alternative to unit cell based modelling methodologies [39-41]. However, modelling at the RVE level has been known to exhibit reduced accuracy due to the lack of geometric detailing [39].

The Binary Model [42-44] attempts to move away any assumptions of periodicity within the material. It was used for simulating relatively large, three-dimensional models of textile composites, whilst paying particular attention to the induced stochastic flaws introduced into the material during manufacturing. The model uses beam elements to represent fibre tows, which are then embedded within a solid effective medium that represents the matrix. The Binary Model can incorporate non-linearity in both the reinforcing tow and matrix easily, and was shown to reproduce well the qualitative features of stress-strain curves for uni-axial tests

on a 3D woven angle interlock material. Readers are referred to [45] for a more comprehensive overview of modelling strategies for 3D woven composite materials.

The experimental component of this paper utilises uni-axial tension and compression tests and a cantilever beam bending test. By varying the length of beam during the cantilever beam test, two distinct collapse mechanisms experienced by orthogonal 3D woven composites during out-of-plane loading were isolated. Two different densities of orthogonal through-the-thickness reinforcement were tested. The numerical method is developed as a viable finite element strategy for modelling full scale 3D woven composites test coupons. The FE model aims to be computationally efficient, utilising embedded shell elements representing the reinforcement tows within solid matrix elements.

2. 3D woven composite material and in-plane tension/compression coupon tests

This study used 3D orthogonal woven carbon fibre reinforcements with two through-the-thickness (TTT) binder densities. The two different fibre architectures are shown in Figure 1. The “Full TTT” material has a binder-to-warp-stack ratio of 1:1 (i.e. each binder tow being separated by one vertical stack of warp tows), while the “Half TTT” material has a binder-to-warp-stack ratio of 1:2. Throughout this paper, the warp tow direction is referred to as the x-direction, the weft tow direction is referred to as the y-direction and the through-the-thickness direction is referred to as the z-direction. Microscopic images of the cured composite cross-sections were used to measure the average values for the dimensions of the fibre architecture. The average dimensions are presented in Figure 1. Both materials contained an alternating stack of 9 weft layers and 8 warp layers giving a total thickness of 3.5 mm for the cured composite. The overall fibre volume fraction was 0.56 for the full TTT composites, and 0.55 for the half TTT composites. The carbon fibre tows were AKSACA A-38 with 6K filaments for warp and weft tows, and 3K filaments for binder tows. Epoxy resin was Gurit Prime

20LV, with the ratio of slow hardener to resin by weight as 26:100. Standard vacuum infusion technique was utilised for the resin injection. Further details of the composite material are presented by Turner et al. [46].

Quasi-static (2mm/min) uniaxial material coupon tests were conducted on the Full TTT 3D woven composites, in order to determine the in-plane mechanical properties under tension and compression. The in-plane tension and compression experimental procedure was identical to that presented by Turner et al. [46], adopting EN ISO 527-4 methodology for tensile testing, and ASTM D3410/B for compression testing. Five repeat measurements were taken for tension and compression tests in warp and weft directions. The tensile and compressive tests in the $\pm 45^\circ$ orientation were performed in a way that warp and weft tows lay at $\pm 45^\circ$ to the loading axis.

3. Cantilever beam test protocol

Figure 2(a) presents a sketch of the cantilever beam set-up. Beam specimens of width $w = 20$ mm were cut along both directions (longitudinal warp or weft yarns), from the two different 3D woven composites panels. One end of the beams was clamped into a custom-designed fixture in stainless steel with M6 bolts. This fixture was subsequently bolted onto a steel I-Beam attached to an Instron 5581 test machine with a static 50 kN load cell. The Instron test machine provided a constant displacement rate at 4mm/min for a 10 mm diameter roller in constant contact with the free end of the beams. The diameter of the loading roller was chosen to match current 3-point [47-49] and 4-point [47] flexural test method standards. The roller diameter was deemed large enough to reduce local surface fibre damage caused by contact stresses. Initial testing indicated that the length of the cantilever beam that extended past the roller loading position had no influence on the response of the beams. The front surface of the beams were speckle painted for DIC analysis. Figure 2(b) presents a sketch of

the cantilever beam test orientated along the x-direction (warp) showing the fibre reinforcement topology in relation to the beam.

4. Finite element Analysis

A FE modelling strategy, used for the prediction of the in-plane and out-of-plane responses of the orthogonal 3D woven carbon fibre reinforced composite, will now be presented. The primary aims of the numerical calculations presented in the following sections are:

- To examine the efficacy of the embedded element modelling technique employing the constitutive models of Matzenmiller et al. [50] and Hashin [51] for fibre composites.
- To provide in-depth understanding of the experimental results.

4.1 FE model of orthogonal 3D woven composites

A three dimensional (3D) finite element analysis was conducted by using the explicit solver in ABAQUS (Version 6.12). Each individual tow in weft, warp and TTT-directions was modelled with 4-noded doubly curved shell elements (S4 in ABAQUS notation), with five integration points through the thickness. The length of side of each element was 0.25 mm. See Figure 3 for a sketch of the meshed finite element model. The orientation option within ABAQUS was used to assign the local fibre orientations of individual tows. The geometric data for defining the locations and cross sectional areas of the tows or TTT-reinforcement were taken from microscopic images. The fibre architecture varies throughout the structure due to the presence of the binder and randomly orientated stochastic flaws. Therefore, an average was taken in order to recreate the geometry of the specimen in the FE model. The matrix was modelled using quadratic solid elements (C3D8 in ABAQUS notation) of second-order accuracy. The total number of shell and solid elements was 91,000 elements for the short beam model, and 474,000 elements for the long beam model; a numerical study

demonstrated that this mesh density achieved a converged result. Shell elements, representing the reinforcement tows, were embedded within the solid elements, which represents the resin matrix. The translational Degrees of Freedom (DoF) of the nodes in the shell elements are constrained to the interpolated values of the corresponding DoF in the solid elements (host elements).

For cantilever beam simulation, the loading roller was simulated as a discrete rigid body (using R3D4 elements in ABAQUS notation). The roller was moved along the z-direction with a constant displacement. General contact option in ABAQUS was used to model the interaction between the roller and the cantilever beam with a tangential friction coefficient of 0.3. The translational degrees of freedom of the matrix, and the translation and rotational degrees of freedom of the tows were constrained at the clamped end of the beam simulations. This gave a free length of 8 mm for short beam calculations and 40 mm for long beam calculations. Simulations were conducted on 40 mm length long beams, as opposed to the longest beam length tested, in order to reduce calculation time. For the simulation of the in-plane tension and compression tests, the translational degrees of freedom of the edge of the matrix, and the translation and rotational degrees of freedom of the edge of the tows were constrained at one end of the sample, and the other end subjected to a constant displacement along either the x or y-direction. The simulations were conducted in parallel mode (8 CPUs) using the High Performance Computing (HPC) facility at the University of Nottingham.

The constitutive models of Matzenmiller [50] and Hashin [51] for fibre composites were employed to capture the observed collapse modes of tows and TTT-reinforcement. Plane-stress elastic properties were employed for the tow and TTT reinforcement. As the stress state within the elements surpass the Hashin damage initiation criteria damage locus, four scalar damage variables, corresponding the four damage modes, are introduced to represent the

effects of the damage modes. Post initiation of damage, the response of the material is

$$\text{governed by } \begin{cases} \varepsilon_{11} \\ \varepsilon_{22} \\ \gamma_{12} \end{cases} = \begin{cases} 1/[\bar{E}_{11}(1-d_f)] & -\bar{\nu}_{21}/[\bar{E}_{11}(1-d_f)] & 0 \\ -\bar{\nu}_{12}/[\bar{E}_{22}(1-d_m)] & 1/[\bar{E}_{22}(1-d_m)] & 0 \\ 0 & 0 & 1/[\bar{G}_{12}(1-d_s)] \end{cases} \begin{cases} \sigma_{11} \\ \sigma_{22} \\ \sigma_{12} \end{cases} \quad (1)$$

$$\text{where } d_f = \begin{cases} d_f^t & \text{if } \sigma_{11} \geq 0 \\ d_f^c & \text{otherwise} \end{cases} \quad \text{and} \quad d_m = \begin{cases} d_m^t & \text{if } \sigma_{22} \geq 0 \\ d_m^c & \text{otherwise} \end{cases} \quad (2)$$

Here, d_f^t , d_f^c , d_m^t and d_m^c are the damage variables for fibre damage under tension and compression, matrix damage under tension and compression, respectively. d_s is the shear damage variable, defined as

$$d_s \equiv 1 - (1 - d_f^t)(1 - d_f^c)(1 - d_m^t)(1 - d_m^c) \quad (3)$$

The shear damage variable is used later in order to visualise the location of damage during finite element simulations of in-plane uni-axial coupon tests. It is useful as a “resultant” damage variable combining tension and compression for both longitudinal and transverse directions. The behaviour of the tow and TTT reinforcement elements post-damage is governed by a linear softening relationship, as determined by the materials fracture energy. A characteristic length scale across a finite element, l_e , is included in order to help alleviate mesh dependency. A more detailed description of the constitutive laws employed within the finite element modelling in this study is presented in the supplementary data to this paper.

The matrix was treated as a J2-flow theory based elastic-ideally plastic material. A critical Von Mises effective strain was used for damage initiation. Post damage initiation, a damage variable, D , was employed for the linear degradation of the elasticity, i.e. $(1-D)E_m$, and for the linear softening of the yield stress, i.e. $(1-D)\hat{\sigma}_Y^o$. The post damage initiation behaviour of the material is governed by the matrix fracture energy. The matrix was split into 17 layers

through the thickness, representing each of the 17 individual layers of the fibre reinforcement. A cohesive contact law was used to model the interface between the layers. This simulates the traction-separation behaviour between them and allows the FE model to capture delamination at these locations. It is noted that it was at these locations that delamination occurred during experimental testing. An uncoupled quadratic maximum stress damage initiation criterion was used, and a linear softening law employed post damage initiation with the behaviour governed by the defined fracture energy. The values for the parameters of the cohesive law are presented in the supplementary data to this paper. A detailed description of the constitutive models with the finite element strategy, and of the derivation of the material properties, is presented in the supplementary data to this paper. In short, the majority of the material properties for the fibre reinforcement were calculated from uni-axial tension and compression tests, and the matrix material properties were taken from manufacturer's data and uni-axial coupon tests with the fibre reinforcement orientated at $\pm 45^\circ$ to the loading axis. The values used for the material properties are also presented in the supplementary data to this paper.

5. Results and discussion

5.1 *Collapse of coupons during in-plane tension and compression loading*

Characteristic tensile and compressive stress-strain curves of the 3D woven carbon composite are presented in Figure 4. The measured Young's Modulus in the tensile tests were 44.3 and 74.6 GPa for warp and weft directions, respectively. The tension and compression tests showed elastic-brittle fracture both in the warp and weft directions. This was governed mainly by fibre reinforcement fracture, as being observed from scanning electron microscopic (SEM) images of the fracture surfaces. Fracture occurred at the location of the TTT-reinforcement for both compression and tension testing of samples orientated along the

y-direction (weft). Fracture location was attributed to stress concentrations due to crimping of longitudinal tows at the TTT-reinforcement location. No significant delamination, and no buckling of plies was recorded during these tests. Material tests conducted with fibres orientated at $\pm 45^\circ$ show a weaker but more ductile response as they are governed by the relatively soft matrix material. This is consistent with the behaviour observed by Gerlach et al. [21] for an orthogonal 3D woven carbon composite material tested with fibres orientated $\pm 45^\circ$ to loading direction.

For model validation, finite element calculations of in-plane tension and compression test coupons were conducted. Good fidelity between the finite element modelling and experimental measurements was achieved, and the predictions are presented alongside the experimental results in Figure 4. The FE simulation captures the stiffness and peak stress of uniaxial compression/tension tests. The FE model can also provide further insights into the nature of the collapse event within the material. Figure 5(a) presents the predicted contour of in-plane stress along y-direction (weft), σ_{yy} , under y-direction (weft) uniaxial compression testing, immediately prior to failure of the sample. At the positions of the TTT-reinforcement, there is a clear increase in magnitude of σ_{yy} . This is attributed to crimping within the surface weft tows induced by the TTT-reinforcement. The predicted ratio of maximum to minimum stress σ_{yy} in the surface weft tows is approximately 4.0, with the peak stress immediately prior to fracture being identical to that of the longitudinal compressive strength of weft tows, $\bar{X}^C = 1.1$ GPa. This notably high ratio is analogous to the stress concentration factor of 5.5 recorded in notched CFRP samples under compression fatigue loading [52], which is defined as the ratio of local stress to remote stress. To understand the stress distribution through the thickness of the sample, Figure 5(b) shows the contours of σ_{yy} , immediately prior to failure,

within the central weft tow stack, as highlighted in Figure 5(a). Again, both top and bottom surface tows have significant stress concentrations owing to crimping induced by the TTT-reinforcement. However, as the crimping has less influence on the geometries of the internal weft tows than those of the surface tows, the stress concentrations in the internal tows are less significant. The staggered binder location at the top and bottom surfaces of the material causes an alternating pattern of increased and reduced local stresses throughout the thickness of the material. This stress variance leads to the “step” shape fracture phenomena. The location of the fracture surface corresponds to the position of maximum longitudinal stress σ_{yy} shown in Figure 5(a) and follows the stress distribution through the thickness shown in Figure 5(b). Figure 5(c) and (d) show the fractured sample obtained by FE simulation and experiment, respectively. The contour in Figure 5(c) shows the damage variable, d_s , within the tows.

For the same sample under tensile testing along y-direction (weft), Figure 6(a) shows the contours of in-plane stress along y-direction (weft), σ_{yy} , within the top surface layer tows, while (b) shows the shear damage variable, d_s , at the fracture surface of the fibre reinforcement immediately after sample fracture. Although the response was governed by the tensile response of the in-plane tows, the shear damage variable was chosen as it allows a convenient visualisation of a combination of the four damage modes. Once fracture initiates within a longitudinal weft tow, it rapidly propagates throughout the material, through the centre of the TTT-reinforcement. Again, the increase in longitudinal stress, σ_{yy} , at the TTT-reinforcement position gives rise to final fracture. In Figure 6(a), the ratio of maximum to minimum stress σ_{yy} in the weft tow is approximately 1.8, with the maximum stress prior to the onset of fracture being 1.72 GPa which is equal to the longitudinal tensile strength of the

weft tows, \bar{X}^T . The maximum to minimum stress ratio during tensile testing is lower than that of the compressive testing. This is because during the tensile test, the loading acts to “straighten out”, the yarns, thus, reducing the effect of crimp. The FE predication is consistent with experimental observation, i.e. the fracture occurred at a TTT-reinforcement position. Figure 6(b) and (c) presented the prediction and observed fracture surface from the experiment. The contour in Figure 6(b) is the shear damage criterion, d_s , with a value of 1 indicated elements which are fully damaged. The numerical calculation correctly predicts the “step” shape fracture surface, located between two neighbouring crimp positions.

5.2 *Cantilever beam collapse mechanisms*

In order to classify the collapse response of the beams, a set of experiments were conducted with cantilever beams of varying length loaded to failure. Through this, it was possible to identify two distinct collapse mechanisms, and the transition between them. Figure 7(a) presents the force applied by the roller against normalised roller deflection $\bar{\delta} = \delta / L$ along the z-direction for a range of beam lengths. The roller displacement is normalised against the cantilever beam length. Beam collapse is defined as the initial drop-off in resisted load for the shear mechanism, and the drop-off of load resisted after initial period of non-linearity for bending dominated mechanisms. These locations are marked on Figure 7(a). For brevity, only the set of experiments of beams of Full TTT material, with beams orientated along the x-direction (warp) are presented. Beams orientated along the weft direction, and beams of Half TTT material exhibited the same characteristics. The results demonstrate two distinct collapse responses. The short beams, i.e. 7 mm, 8mm, and 10 mm beam lengths, have a linear elastic response up until collapse, and then demonstrate a secondary rise in load resisted before ultimate beam failure. Long beams, i.e. 15 mm, 40 mm and 110 mm, exhibit a softening regime and then an incremental reduction in load resisted until failure. The moment of beam

collapse is highlighted on each of the load-deflection curves presented in Figure 7(a). Figure 7(b) presents the collapse load P_c of the beams as a function of beam length L . The two distinct regimes are visible from the data. Simple beam theory was used to curve fit the effective stress within the beam at collapse. It is presented as an approximation in order to demonstrate the transition between the two regimes, i.e. $P_c^b = \sigma_x W t^2 / 6L$ for bending dominated long beams and $P_c^s = \tau_{xy} W t$ for shear dominated short beams. Curve fitting bending dominated beam theory gave the peak stress at collapse of $\sigma_x = 590$ MPa . This value is seen to correspond well to the longitudinal tensile strength along the x-direction (warp) of the composite material, i.e. $\sigma_x = 595$ MPa (presented in Figure 4(a)). Comparison is made to the tensile strength, as tensile crack propagation was the dominant failure mechanism presented by the long cantilever beams. For the shear regime, curve fitting beam theory gave an average shear stress at collapse of $\tau_{xy} = 46$ MPa . The matrix dominated response of tensile coupon tests with fibres orientated at $\pm 45^\circ$ to the loading axis (Figure 4(a)) predicts the matrix strength at the onset of non-linearity of the test demonstrated to be 80 MPa. Assuming the shear strength to be half of this value, i.e. $\tau_{xy} = 40$ MPa , corresponds acceptably with the collapse response demonstrated during the cantilever beam tests. However, in reality the composite material demonstrates a highly non-linear shear response [53], and therefore this value is only used as a guide. In Figure 7(b), the transition beam length between shear and bending dominated collapse regimes is estimated to be approximately $L \approx 12.5$ mm. For the detailed study, beam lengths 8 mm and 40 mm were selected as representative of shear dominated collapse and bending dominated collapse mechanisms, respectively.

5.3 Long cantilever beam bending collapse

As previously demonstrated, the collapse behaviour of the long cantilever beams is governed by bending deformation rather than by shear deformation. Figure 8(a) and (b) show the force imposed by the roller as a function of roller displacement along z-direction for long (40 mm) cantilever beams for Full TTT and Half TTT material orientated along the x-direction (warp) and y-direction (weft), respectively. Also presented is the FE prediction of a long (40 mm) beam collapse event for a Full TTT beam orientated along the x-direction (warp). For both orientations, there was shown to be no significant difference between the two materials tested. To understand the failure mechanism of the long beams, Figure 8(c) shows the full field strain measurement ϵ_{xx} for normal strain along x-direction (warp) on the front surface of the beam, acquired by the Digital Image Correlation (DIC) technique, for the composite beam with Full TTT reinforcement orientated along the x-direction (warp). The images can be related to the corresponding load – displacement relation shown in Figure 8(a). In the elastic region, up to point A, there are localised increases of tensile strain at the top of the beam. These locations correspond to the positions of TTT reinforcement in the specimen. The load-displacement response became non-linear from point A to Point B, which corresponds to an increase in local compressive strain at the bottom of the beam. Optical microscopic images of the beam post-test, presented in Figure 8(c), reveal the presence of fibre microbuckling of longitudinal tows and crushing of a transverse tow at the clamped edge. Post peak load, at Point C, a tensile crack initiates at the clamped location. Progressive drop-off in load resisted by the beam is attributed to the propagation of the tensile crack. No delamination was observed during either the Full TTT or the Half TTT long beam cantilever tests. The failure mode was identical for both warp and weft direction for both binder densities of the long beam test.

For long cantilever beams, Figure 8(a) shows a comparison between experimental measurement and FE predictions of the force imposed by the roller as a function of roller displacement along z-direction with length of the beam, $L = 40$ mm, and thickness, $t = 3.5$ mm. As the characteristics of the behaviour of the warp and weft orientated beams were the same, i.e. initial linear elastic behaviour followed an a period of non-linearity and progressive reduction in load resisted by the beam, for brevity, only the numerical calculations of the beam oriented along warp direction is presented. The agreement between experimental measurements and FE predictions is reasonably good. Figure 8(d) shows the montage obtained by FE calculations with contour representing strain along x-direction, ϵ_{xx} . As expected, the long beam failed under bending mechanism, i.e. tensile failure within top tows and compressive failure within bottom tows. At Point A, immediately prior to peak load, there is seen to be an increase of local compressive longitudinal strain at the bottom of the beam at the clamp position. Between Point A and Point B there is a rapid drop-off in load resisted by the beam, caused by an increase of tensile fibre damage of longitudinal warp tows at the top of the beam. This corresponds well to the tensile crack recorded during experimental testing. Tensile fibre damage is the cause of the local increase in tensile longitudinal strain at the top of the beam, seen at Point B. It is proposed that the modification of the linear softening compressive damage evolution law in compression is necessary to fully capture the post damage response of the cantilever beam, i.e. the non-linearity due to kink band formation and tow buckling. In between Point C and D, the FE prediction captures progressive, sudden reductions in load resisted by the beam. The FE model identifies these load reductions to the successive compressive damage of tows located at the clamp. The numerically predicted buckling length of warp tows at the bottom of the beam was approximately 1.5 mm, this coincides to the gap in between TTT-reinforcement positions. Figure 9(a) shows a μ -CT image of the tensile bending crack within the long cantilever beam

post-test. Beam was Full TTT material orientated along the x-direction (warp). The image shows the bending crack following the edges of the TTT reinforcement. The long cantilever beam bending collapse response of a UD-laminate material is presented in the supplementary data to this paper (Figure S.1). In short, the UD-laminate material exhibited extensive delamination throughout the entire length of the beam after initial collapse. This differs from the collapse mechanism demonstrated by the 3D woven composite material.

5.4 Short cantilever beam bending collapse

As previously demonstrated, the collapse behaviour of the short cantilever beams is governed by a shear dominated mechanism. Figure 10(a) and (b) shows the force imposed by the roller as a function of roller displacement along the z-direction for the short cantilever beams with Full and Half TTT 3D woven composites, with beams orientated along x-direction (warp) and y-direction (weft), respectively. The shaded areas represent the range of 3 individual test repeats. For both beam orientations, the density of the TTT reinforcement has small effect on the load-displacement relationship of the short cantilever beams. The Full TTT beams are shown to exhibit a marginally higher secondary increase in load resisted after the initial collapse. DIC images showing the shear strain, γ_{xz} field are shown in Figure 10(c) for the Full TTT reinforcement beams orientated along the x-direction (warp). As shown in Figure 10(a) and (c), up to point A the load-displacement response is linear elastic, with local increases in inter-ply shear strain. After the peak load at point B, delamination occurs around the neutral axis of the beam and TTT reinforcement, where shear strain is higher than at other locations. This delamination continues to point C, where the tows on the top of the beam begin to fracture under tensile stress.

At point D, the beam has begun to fail by fibre fracture on the top of the beam, with significant development of inter-laminar shear strains (see the peak shear strain locations in D

of Figure 10(c)). The large tensile crack propagates at and after the point of peak load, widening until ultimate catastrophic failure of the beam. Shown by a comparison between Figure 10(a) and (b), beams orientated along the x-direction (warp) are seen to have a more rapid drop off in load resisted, compared to the gradual load-bearing reduction of beams orientated along the y-direction (weft).

Figure 10(d) presents the finite element prediction of the short beam collapse event, as shown experimentally in Figure 10(c). The shear strain field γ_{xz} is shown. Up until point A, the prediction of the beam shows elastic deformation, which agrees well with experimental results. At Point B, a hinge forms in the FE predictions at the clamped end of the beam due to damage of the top warp tows and cohesive interaction. The shear strain field is shown to be almost identical to the shear strain field measured by DIC during experimental testing, i.e. Point B in Figure 10(c). The local strain is shown to be higher at the neutral axis and locations of TTT reinforcement. At point C, delamination has propagated longitudinally along the beam. However, the development of delamination is different from that observed in the experiment. During the experiment, the delamination propagates throughout the entire length of the beam, and this is not captured within the FE model. It is suggested this discrepancy is due to the use of an oversimplified constitutive model for the cohesive interaction, and lack of simulated confinement pressure from the TTT reinforcement and subsequent increase in frictional forces between composite layers. Finite element calculations also reveal the effect of TTT reinforcement on the load versus vertical roller deflection relation is small. The final image at point C of the FE prediction of the short beam collapse event along the warp direction without TTT reinforcement is presented in Figure 10(e). The prediction of the beam collapse with TTT reinforcement removed shows uninhibited delamination growth. However, this did not significantly affect the load-displacement

response. The numerically predicted delamination length for the Full TTT case was 3.0 mm; this corresponds well to the experimentally measured delamination length of 2.8 mm. The numerical prediction of the delamination length of the No TTT material was 5.5 mm. However, due to the reasons mentioned before, the model is not able to capture the secondary increase in load resisted.

In order to investigate the damage mechanisms throughout the beam thickness, Cross sectional X-Ray μ CT scans of the beam post-testing are presented in Figure 11. Section a-a, a scan in between the binder position, demonstrates localised delamination, the length of which was bounded by the distance between TTT reinforcement tows. Section c-c, a scan also in between the binder position, did not demonstrate localised delamination, only tensile cracking. This highlights the heterogeneity and localisation of damage within the beam. At cross-sections located through the TTT reinforcement, for example scan b-b, no localised delamination was recorded. However, the tensile cracking was shown to be more pronounced at this location. These scans reveal localised, damage within the composite material. The short cantilever beam collapse response of a UD-laminate material is also presented in the supplementary data to this paper (Figure S.2). In short, delamination was recorded to propagate throughout the entire width of the UD-laminate composite beam, as opposed to the suppressed, localised delamination of the 3D woven composite beams.

6. Concluding remarks

The collapse response of orthogonal 3D woven composites was investigated during in-plane tension and compression and out-of-plane bending load cases. The cantilever beam test has been shown to be effective in isolating the two collapse mechanisms of orthogonal 3D woven composite materials; bending dominated long beam tests, and shear dominated short beam tests.

The TTT reinforcement of 3D woven composites prevents delamination with long cantilever bending tests, and provides containment and limited changes to the post-peak load response with short beam tests. Localised delamination is shown in short cantilever beam tests, however, in long beam tests the failure mechanism is a large tensile crack and compressive buckling of longitudinal fibres at the clamped end. DIC analysis indicates increased local strain at TTT reinforcement positions for both long beam and short beam tests due to the presence of matrix pockets.

A finite element modelling strategy is presented and validated with experimental results of in-plane tension and compression test and cantilever bending tests. The FE method demonstrated excellent fidelity for in-plane uni-axial tension and compression tests. High levels of fidelity are also shown for the stiffness and peak load of long and short cantilever beam tests. However, the model is unable to capture the post initial peak load response of the short cantilever beam tests. Refinements to the cohesive interaction and damage evolution laws are suggested for advancements of the modelling strategy.

Acknowledgements

3D woven fabrics were provided by Sigmalex UK. The authors acknowledge support from the Engineering and Physical Sciences Research Council, UK (EPSRC EP/P505658/1 and EP/K503101/1) and Early Career Research and Knowledge Transfer Awards from the University of Nottingham. They also acknowledge the use of the High Performance Computing facility at the University of Nottingham for finite element calculations.
